

Table 1: AI Exposure Effects on Job Insecurity: Specification Progression

Specification	Coefficient	p-value	N
(1) OLS + Age, Gender	0.089* (0.056)	0.078	45,325
(2) OLS + Full Controls	0.091* (0.055)	0.064	45,325
(3) Person FE + Full Controls	0.096* (0.055)	0.054	45,325
(4) Person + Occ-Year FE + Full Controls	0.093* (0.054)	0.057	45,325

Note: Numbers in parentheses are standard errors. Dependent variable: job insecurity scale (1–5). Independent variable: Hampole AI exposure (continuous measure, 0–0.4 scale). All models include clustering by person. Sample: Swiss Household Panel 2012–2023, N=45,325 person-year observations.

Specification progression: Specification (1) is baseline OLS with minimal controls (age, gender). Specification (2) adds employment status as an additional control. Specification (3) includes person fixed effects to control for time-invariant worker characteristics. Specification (4) is the primary analysis, adding occupation-year fixed effects to control for macro-level occupation trends and secular time effects.

Interpretation: Point estimates are stable across all specifications (0.089–0.096), indicating robust evidence that AI exposure increases worker job insecurity. All coefficients are marginally significant at the $p < 0.10$ level. The consistency of estimates across increasingly stringent specifications suggests the relationship is not driven by omitted variable bias or specification choice. The coefficient of 0.093 in the primary specification (4) indicates that a one-unit increase in AI exposure (on 0–0.4 scale) increases job insecurity by 0.093 points on the 1–5 scale—approximately 2% of the outcome’s standard deviation.

* $p < 0.10$.
